Is there anything interesting to say a bout
representations as knot groups into braid

$$
\text { grays } l_{0}
$$

Any such rypresuntition would correspond to
a "ron-standurd cabling operation", in
which the knot is replaced by the representation applial to its longtitub.

Is there a relationship buturon the $w$ of $\beta$-calculus \& contact gromdry?

I need a framework for the "sum of columns" condition in beta-calculus:

- Why is it there?
- Is it really there, even when vertices are present?
- Can it be exploited systematically?
